8 Abstract

9 East African countries face an increasing threat from poor air quality, stemming from rapid
10 urbanisation, population growth and a steep rise in fuel use and motorization rates. With few air
11 quality monitoring systems available, this study provides the much needed high temporal resolution
12 data to investigate the concentrations of particulate matter (PM) air pollution in Kenya. Calibrated
13 low cost optical particle counters (OPCs) were deployed in Kenya in three locations: two in the
14 capital of Nairobi and one in a rural location in the outskirts of Nanyuki, which is upwind of Nairobi.
15 The two Nairobi sites consist of an urban background site and a roadside site. The instruments were
16 composed of an AlphaSense OPC-N2 optical particle counter (OPC) ran with a raspberry pi low cost
17 microcomputer, packaged in a weather proof box. Measurements were conducted over a two-
18 month period (February – March 2017) with an intensive study period when all measurements were
19 active at all sites lasting two weeks. When collocated, the three OPC-N2 instruments demonstrated
20 good inter-instrument precision with a coefficient of variance of $8.8 \pm 2.0\%$ in the $PM_{2.5}$ fraction. The
21 low cost sensors had an absolute PM mass concentration calibration using a collocated gravimetric
22 measurement at the urban background site in Nairobi.
23 The mean daily PM_1 mass concentration measured at the urban roadside, urban background and
24 rural background sites were 23.9, 16.1, $8.8 \mu g m^{-3}$. The mean daily $PM_{2.5}$ mass concentration
25 measured at the urban roadside, urban background and rural background sites were 36.6, 24.8, 13.0
26 $\mu g m^{-3}$. The mean daily PM_{10} mass concentration measured at the urban roadside, urban background
27 and rural background sites were 93.7, 53.0, $19.5 \mu g m^{-3}$. The urban measurements in Nairobi showed
28 that particulate matter concentrations regularly exceed WHO guidelines in both the PM_{10} and $PM_{2.5}$
29 size ranges. Following a 'Lenschow' type approach we can estimate the urban and roadside
30 increments that are applicable to Nairobi. Median urban and roadside increments are 33.1 and 43.3
31 $\mu g m^{-3}$ for PM_{10} , respectively, the median urban and roadside increments are 7.1 and $18.3 \mu g m^{-3}$ for

1 PM_{2.5}, respectively, and the median urban and roadside increments are 4.7 and 12.6 $\mu\text{g m}^{-3}$ for PM₁,
2 respectively. These increments highlight the importance of both the urban and roadside increments
3 to urban air pollution in Nairobi.
4 A clear diurnal behaviour in PM mass concentration was observed at both urban sites, which peaks
5 during the morning and evening Nairobi rush hours; this was consistent with the high measured
6 roadside increment indicating that vehicular traffic is a dominant source of particulate matter in the
7 city, accounting for approximately 48.1, 47.5, and 57.2% of the total particulate matter loading in
8 the PM₁₀, PM_{2.5} and PM₁ size ranges, respectively. Collocated meteorological measurements at the
9 urban sites were collected, allowing for an understanding of the location of major sources of
10 particulate matter at the two sites. The potential problems of using low cost sensors for PM
11 measurement without gravimetric calibration available at all sites are discussed.
12 This study shows that calibrated low cost sensors can be used successfully to measure air pollution
13 in cities like Nairobi. It demonstrates that low cost sensors could be used to create an affordable and
14 reliable network to monitor air quality in cities.

15 1. Introduction

16 Recently, the Lancet Commission on pollution and health estimated that in 2015, air pollution led to
17 the premature deaths of over nine million people globally, and attributed to over one in four deaths
18 in severely affected countries (Landrigan et al., 2017). Typically, urban air pollution is higher in low
19 and middle-income countries (LMICs) compared to further developed countries. Hence, the
20 associated risk of air pollution to health is typically higher in LMICs, with over 92% of global pollution
21 related deaths occurring in these countries. Within LMICs, health inequalities in urban areas
22 contribute to an increased exposure to air pollution that faces those that live, work, socialise and
23 commute to highly urbanised areas which typically have a substantially higher concentration of air
24 pollutants. Despite the extensive links between air pollutants and human health, environmental
25 degradation and the economy, air pollution is as of yet still under-researched in many LMICs. Due to
26 a lack of long term air quality monitoring in many LMICs, the concentrations and sources of air
27 pollution are poorly understood.

28 Airborne particulate matter (PM) air pollution is a major environmental risk factor with well-
29 documented short and long-term effects on human mortality and morbidity (Thurston et al., 2016).
30 It is known to affect asthma, chronic pulmonary disease (COPD), pulmonary fibrosis, cancer, type-2
31 diabetes, neurodegenerative diseases, obesity and other conditions (Ferranti et al., 2017). The size
32 of PM is correlated with their health impacts, with smaller particles typically having more significant
33 health implications (Meng et al., 2013). PM₁, PM_{2.5} and PM₁₀ are particulate matter with

1 aerodynamic diameters less than 1, 2.5 and 10 μm , respectively (Seinfeld and Pandis, 2016). The
2 World Health Organization (WHO) recommends that $\text{PM}_{2.5}$ and PM_{10} daily mass concentrations
3 should not exceed 25 and 50 $\mu\text{g}/\text{m}^3$, respectively; and that annual mass concentrations do not
4 exceed 10 and 20 $\mu\text{g}/\text{m}^3$, respectively (WHO, 2006). At present, the WHO or other regulatory bodies
5 do not provide recommendations of the mass concentrations of PM_1 . PM_1 can remain suspended in
6 air for much longer than coarser particulate matter, as well as penetrating deeper into the lungs
7 leading to local pulmonary, systematic inflammation (Pateraki et al., 2014). Due to the smaller size,
8 PM_1 has a higher surface to mass ratio, containing a harmful amount of potentially toxic
9 anthropogenic constituents which could lead to health impacts such as respiratory disease, heart
10 disease and lung cancer (Trippetta et al., 2016). Many studies still focus on PM_{10} and $\text{PM}_{2.5}$ even
11 though smaller particulates pose greater health impacts (Tsiouri et al., 2015). Beyond PM_1 , ultra-fine
12 particles ($<100\text{ nm}$) are of such a small size they can be translocated to the central nervous system
13 via the blood to brain barrier or the olfactory bulb. There are no air quality regulations of PM_1 or
14 ultra-fine particles due to the paucity of data either within environmental science or public health.

15 Worldwide, road traffic is a dominant source of urban PM accounting for 5-80% of PM mass, with
16 the precise amount being dependent upon several factors including time, location, and vehicle fleet,
17 as reviewed by Pant and Harrison (2013). Vehicle derived PM is directly associated with negative
18 health outcomes (Fan et al., 2006; HEI, 2010). Emissions are due both to exhaust pipe emissions and
19 non-exhaust pipe emissions. Exhaust emissions result from the combustion of fuel, predominantly
20 petrol and diesel, and oil and other lubricants. Non-exhaust emissions come either from the
21 resuspension of road dust through wind or vehicle induced wind shear, or from the wear and tear of
22 vehicle parts including the brakes, tyres and clutch. Resuspension of dust is particularly important
23 on non-paved roads of which there are an abundance in Nairobi. Typically, non-exhaust emissions
24 are in the coarse PM size fraction (PM in the size range 2.5-10 μm aerodynamic diameter), whereas
25 exhaust emissions are in the fine PM size fraction ($\text{PM}_{2.5}$) (Thorpe et al., 2007; Kam et al., 2012).
26 However, it is noted that the papers which reference vehicle PM size distributions according to the
27 emission of non-exhaust sources have typically been conducted in either the US or European studies
28 and not in Nairobi or Africa, where non-paved road sources represent a much higher fraction of road
29 surface type. The precise size of vehicular derived PM is dependent on several factors: vehicle fleet
30 characteristics (e.g. weight and size), road type and level of maintenance and meteorological
31 conditions (Beddows et al., 2009; Hays et al., 2011).

32 In many LMIC cities, urbanization, population, fuel use and motorization rates are all increasing
33 rapidly and increases in air pollution are associated with these trends (Mitlin and Satterthwaite,

1 2013;Ochieng et al., 2017). In particular, vehicular traffic is fast on the rise, with associated
2 congestion on the road networks, which can contribute as much as 90% of air pollution in urban
3 environments (UNEP, 2005). Nairobi is the capital city of Kenya and is showing these trends. In
4 particular, the city population has increased dramatically, since 1999 to 2015 it has risen by 83%, and
5 is projected to increase to 7.14 million by 2030 (Rajé et al., 2017). Similarly, motorization rates are
6 increasing, between 2008 and 2012, the number of motor- and auto-cycles in Kenya grew by 368%
7 with the number of overall registered vehicles increasing by 77% (Rajé et al., 2017). Considering this
8 extensive increase in the vehicle fleet, limited roadway infrastructure and high congestion within the
9 city, pollution hotspots are created leading to personal exposure levels much higher than that
10 encountered throughout the rest of the city (van Vliet and Kinney, 2007).

11 To be able to reduce air pollution, you first have to be able to measure it. Many LMIC countries have
12 insufficient monitoring networks through which to measure air quality. In particular, long term high
13 resolution data is required for such cities which are vulnerable to air pollution. Nairobi is in the
14 vanguard of air pollution measurements for Sub-Saharan Africa but lacks continuous long term
15 calibrated measurements of PM and other air pollutants (Petkova et al., 2013). A discussion of the
16 relevant measurements in Nairobi is given in the next section. One of the constraints to making
17 measurements is the high cost of research grade air quality monitoring equipment with appropriate
18 calibration and certification. Low cost sensors offer the potential for dramatically reducing
19 equipment costs by orders of magnitude, making the monitoring of air quality more accessible and
20 attainable in LMIC countries (Lewis et al., 2016;Rai et al., 2017).

21 In this paper, the use of low cost sensors for measurement of PM₁, PM_{2.5} and PM₁₀ in Nairobi is
22 detailed. We have previously assessed the same low cost sensors in the UK (Crilley et al., 2018). The
23 sensors are calibrated using a standardised gravimetric approach. PM is measured in three locations:
24 an urban roadside site, an urban background site and a rural background site. Comparison of
25 simultaneous measurements at the three sites allows for the estimation of an urban increment and
26 roadside increment in PM following a 'Lenschow' type approach (Lenschow et al., 2001). The
27 variation of measured PM with measured meteorological data is also discussed. Finally, we discuss
28 the implications of using low cost sensors in Nairobi and LMIC countries in general.

29 **2. Previous PM measurements in Nairobi**

30 In general, long term air quality monitoring in Sub-Saharan Africa (SSA) is rare. Correspondingly,
31 there are only limited PM data sets for East African urban areas; where data does exist estimated
32 concentrations for PM_{2.5} concentrations are typically ca. 100 µg/m³ compared to <20 µg/m³ in most

1 European and North American cities (Brauer et al., 2012). This indicates that urban PM air pollution
2 in East Africa is of a significant health concern.

3

4 In Nairobi, there have been numerous short term measurements of PM over the last decade (Brauer
5 et al., 2012; Kinney et al., 2011; Ngo et al., 2015; Egondi et al., 2016; Gaita et al., 2016) with only one
6 long term continuous measurement (Gaita et al., 2014). To date, most measurements have used
7 gravimetric measurement methodologies to record PM mass concentration in the PM_{2.5} and PM₁₀
8 size fractions. Most measurements indicate PM concentrations in Nairobi regularly exceed the WHO
9 guidelines. At present, there is only one publication in the scientific literature describing the use of
10 low cost sensors in the measurement of PM (de Souza et al., 2017) which monitored air quality in
11 Nairobi at six sites from May 2016 to January 2017. Using AlphaSense OPC-N2's, the authors
12 measured PM₁, PM_{2.5} and PM₁₀ as well as NO₂, NO and SO₂.

13 The study collected PM concentrations at six schools within Nairobi. It reported a PM_{2.5}
14 concentration range between 11 and 21 µg/m³, and a range of 26 to 59 µg/m³ for PM₁₀. The PM
15 concentrations measured during the de Souza study are noticeably lower than of this study for both
16 size fractions. It is worthy of note that the de Souza study collected measurements from May 2016
17 to January 2017, whereas this campaign took place from February to April 2017; the local
18 meteorology may have influenced the discrepancies seen in both recorded PM concentrations.
19 Additionally, the study did not calibrate the monitors, which leads to questions about absolute
20 concentrations and interference from other environmental dependencies (Lewis and Edwards,
21 2016). The collected data from the study appeared noisy, with the authors stating they could not
22 separate the signal from the noise without having access to an air quality measuring reference
23 instrument (they recorded peaks at over 1000 µg/m³). Despite the limitations, it provides a useful
24 comparison to this calibrated study.

25

26 The paucity of long term calibrated measurements has hindered the understanding of long term
27 trends and the influence of seasonal variations in meteorology and other factors. Most published
28 data provide daily averages of PM mass; the lack of higher temporal resolution data precludes the
29 generation of diurnal data which can be useful for identifying individual sources of PM, in particular,
30 vehicular PM which typically tracks traffic and hence peaks during rush hours.

31

32 The longest record of PM concentration in Nairobi is detailed in Gaita et al. (2014). In this work, the
33 authors performed daily measurements of PM_{2.5} at an urban background and suburban site over a
34 two-year period from May 2008 to April 2010 using polycarbonate filters in cyclone sampler (Casella

1 from Bedford, UK). They reported a concentration range of $3 \mu\text{g}/\text{m}^3$ to $53 \mu\text{g}/\text{m}^3$ at the urban
2 background site, with an overall mean of $21 \mu\text{g}/\text{m}^3$ which exceeds the annual WHO limit of $10 \mu\text{g}/\text{m}^3$
3 by a factor of two. The average concentrations of $\text{PM}_{2.5}$ at both sites were found to be 21 ± 9.5 and
4 $13 \pm 7.3 \mu\text{g}/\text{m}^3$, respectively. Chemical composition measurements of the filter samples allowed
5 source apportionment, via positive matrix factorization, to be carried out. The analysis suggested
6 that five major source factors contribute to Nairobi $\text{PM}_{2.5}$: traffic, mineral dust, industry, combustion
7 and a mixed factor. The dominant source factors were mineral dust and traffic which accounted for
8 74% of the particle mass.

9
10 As an update to this study, Gaita et al. (2016) conducted a study on the characterization and size-
11 fractionation of particulate matter and deposition fraction in the human respiratory system in
12 Nairobi using measurements taken in August and September 2007, obtained at the University of
13 Nairobi site. Based on the findings, the concentration levels of airborne particulate matter sampled
14 at the urban background site during the period was found to range between $1 \mu\text{g}/\text{m}^3$ and $78 \mu\text{g}/\text{m}^3$.
15 The average $\text{PM}_{2.5}$ concentration at the site over the entire sampling period was $9.8 \pm 8.5 \mu\text{g}/\text{m}^3$.

16 A densely populated urban area with associated heavy local traffic within Nairobi largely contributes
17 to the city's air pollution build up. Kinney et al., (2011) investigated the impact of vehicular
18 emissions in Nairobi on the concentration of $\text{PM}_{2.5}$, observing a substantial range between $58 \mu\text{g}/\text{m}^3$
19 and $98 \mu\text{g}/\text{m}^3$ across an 11-hour personal exposure along busy roadways and roundabouts. The
20 range could be estimated to be between 45 and $85 \mu\text{g}/\text{m}^3$ for a 24 h sampling due to pollutant
21 dispersion at night. In addition, the study reported a decrease in horizontal dispersion
22 measurements of $\text{PM}_{2.5}$ from $128.7 \mu\text{g}/\text{m}^3$ to $18.7 \mu\text{g}/\text{m}^3$ over 100 m downwind of a major
23 intersection in Nairobi. A vertical dispersion from a street level to a third-floor rooftop in the Central
24 Business District (CBD) showed a decrease in $\text{PM}_{2.5}$ concentration from $119.5 \mu\text{g}/\text{m}^3$ to $42.8 \mu\text{g}/\text{m}^3$.
25 This study clearly highlights that the PM concentration in Nairobi varies considerably over both time
26 and space, which has significant implications for human exposure, see discussion.

27
28 Another study by Ngo et al., (2015) affirmed the contribution of anthropogenic activities on the
29 quality of air in Nairobi. In their study, Teflon filters in $\text{PM}_{2.5}$ samplers (BGI model 400) were used
30 between 2nd August and 18th August 2011 and high concentrations of $\text{PM}_{2.5}$ exposure levels among
31 different groups in Nairobi were reported. According to the study, bus drivers in Nairobi city were
32 exposed to about $103 \mu\text{g}/\text{m}^3$ while those in informal settlements, such as Mathare, reporting
33 exposure levels of about $62.7 \mu\text{g}/\text{m}^3$, an indication that urgent measures needed to be taken to
34 mitigate the impact of air pollution in the city.

1
2 The severity of air pollution in urban centres in SSA is typically even higher in the informal
3 settlements (slums), where acute respiratory tract infections and bronchitis are among the most
4 frequent medical diagnoses (Gulis et al., 2004). Egondi et al., (2016), in their study on air pollution in
5 two informal settlements in Nairobi: Korogocho and Viwandani, reported higher concentration levels
6 of PM_{2.5} in the two slums. Optical counters (TSI DustTrak II model 3530) were used in the study and
7 observed average concentration levels of PM_{2.5} in Korogocho slum, lying west of Dandora, Nairobi's
8 biggest dumping ground, were the highest at 166 µg/m³ and Viwandani, situated North of Nairobi
9 recorded 67 µg/m³.

10 **3. Methodology**

11 **3.1. Site locations**

12 This study utilised three field sites in Kenya, see Figure 1. Two sites were in Nairobi which is the
13 capital of Kenya, covering an area of ca. 696 sq. kilometres and home to approximately 3.5 million
14 residents according to a World Population review conducted in 2016 (Kenya Population, 2016),
15 making it the second most populated city in East Africa after Dar es Salaam, Tanzania. In addition to
16 Nairobi's longstanding popularity as a travel destination, due to its safari and other holiday resorts,
17 the city also acts as East Africa's diplomatic, financial and communication capital (Rajé et al., 2017).
18 Its geographical location is at approximately 1.29° S and 36.82° E. The highest elevation point in the
19 city is at an altitude of 1663m above the ground. As discussed in the introduction, Nairobi is
20 undergoing rapid increases in population and motorization both of which will likely lead to greater
21 PM pollution in the absence of any efforts of mitigation against the pollution. Other significant
22 infrastructure projects such as major road building are currently being undertaken, which will also
23 likely lead to increased PM loadings. Within Nairobi, the two field sites represent an urban
24 background location and an urban roadside location. The other site, a rural background site is
25 located on the outskirts of Nanyuki, a town that is located at an approximate aerial distance of 147
26 km to the north (NNE) of Nairobi and 240 km by road. The sensor boxes were placed in locations free
27 from obstacles, at the three measurement sites, allowing for 360 degrees of air flow.

29 **Site 1: American Wing, University of Nairobi, Nairobi (urban background site)**

30 The first site for data collection in Nairobi was at the American Wing building located in the
31 University of Nairobi, standing at an elevation of 17 m above ground level. Air flow at the site was
32 free from any obstruction as the OPC's were located at an elevated point above the ground. The

1 nearest road is Harry Thuku road which has very few on-road vehicles (no heavy trucks) and it leads
2 to Fairmont Norfolk and Boulevard hotels, and Kijabe Street. Its level is far below the site and the
3 only influence from the few vehicles and the city is highly diluted and dispersed pollutants (Kinney,
4 et al., 2011) in regional air mass.

5

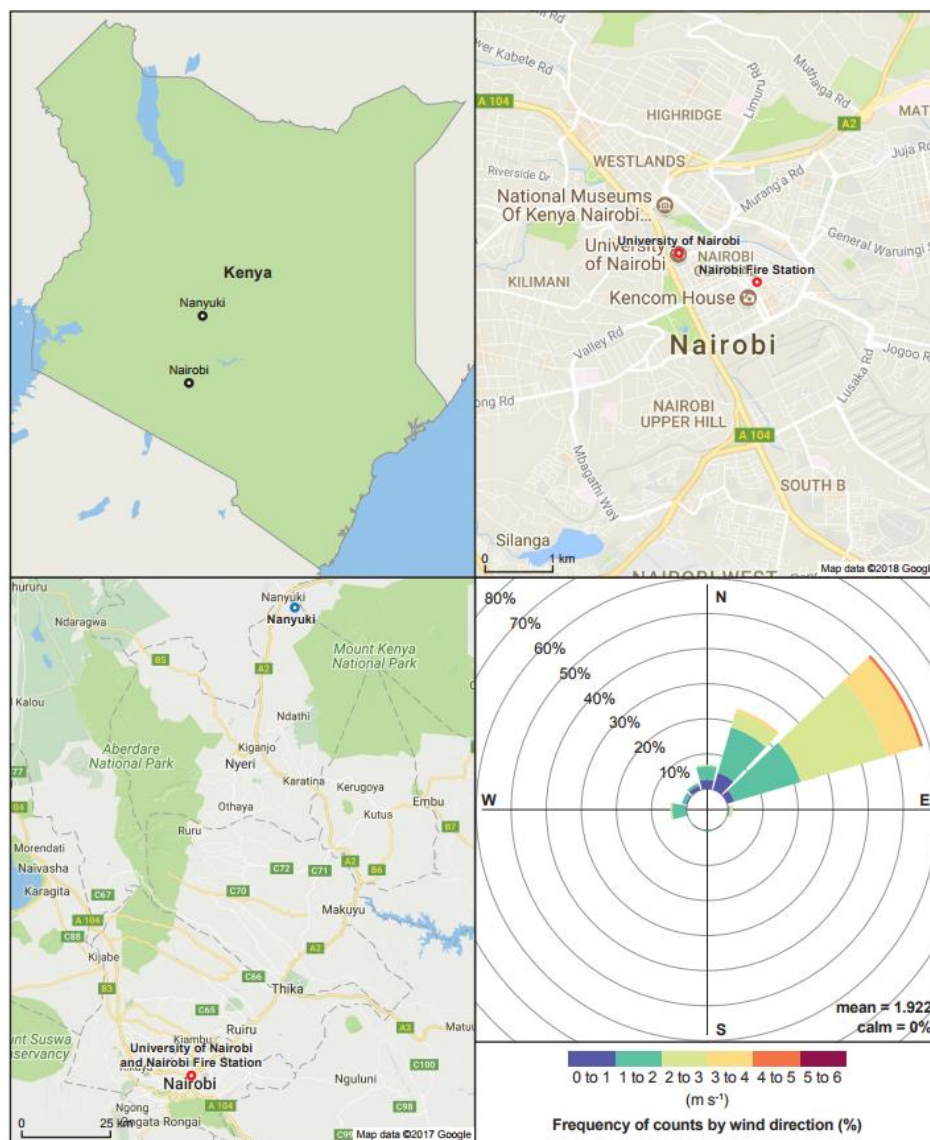

6 **Site 2: Tom Mboya Street, Fire station, Nairobi (urban roadside)**

7 The second collection site in Nairobi was at the fire station, which is located within the CBD in the
8 city. Unlike the American Wing site, the area around the Fire Station is characterized by high traffic
9 flow which includes common public transport vans, locally known by the name “Matatus”. It is on an
10 urban street canyon, on a street where smoking diesel vans are frequent and is exposed to urban
11 heat Island effects. It is also in the neighbourhood of vertical dispersion measurement site of $PM_{2.5}$
12 used by Kinney et al. (2011). The monitor was positioned at a height of approximately 5 m.

13

14 **Site 3: Nanyuki town (rural background)**

15 The third site chosen was on the outskirts of Nanyuki town, an administrative town in Laikipia
16 County which is located to the North West of Mt. Kenya. The town is positioned at the Equator at
17 approximately 1.28° S and 36.01° E. The highest point in Nanyuki is at an elevation of 2000 m above
18 ground level. The town is home to approximately 50,000 people as per the last census conducted
19 (KNBS, 2015). The Nanyuki region has a hinterland of significant agricultural cultivation, forest and
20 considerable grazing activities (Gatari et al., 2005). The OPC was hung about 4 m above ground level
21 thus exposing it to free regional air mass in an area of minimal local influence.

1

 3 **left panel and bottom left panel: locations of Nairobi and Nanyuki in Kenya. Top right panel:**
 4 **shows relative locations of urban background location (University of Nairobi, American Wing) and**
 5 **urban roadside location (Nairobi fire station). Bottom right panel: wind rose generated from data**
 6 **collected at the urban background location during the measurement campaign.**

7
 8

1 **3.2. PM Measurement Equipment**

2 Small low cost optical particle sensors (AlphaSense, OPC-N2, firmware version 18) were used to
3 measure PM concentrations. The AlphaSense OPC-N2 sensors are henceforth referred to as OPC-N2.
4 The OPC-N2 is a miniaturized OPC which has dimensions of 75×60×65 mm and weighs under 105 g.
5 The unit cost of an OPC-N2 is approximately 250 GBP or 25000 KeS, hence it is significantly cheaper
6 than reference optical particle counter instruments which cost approximately 30-50 times as much.
7 Reference grade gravimetric instruments can cost even more. The lower cost of the OPC-N2,
8 provided the opportunity for measurements at multiple sites simultaneously. It measures particles in
9 the reported size range of 0.38 to 17 µm across 16 size bins, with a maximum particle count of
10 10,000 per second. The particle number concentration is converted by on-board factory calibration
11 to PM concentrations according to European Standard EN481 (OPC-N2 manual).

12

13 The assumed density for all particle sizes is 1.65 g/cm³ and no special weighting is placed on any
14 particular bin size. However, the manual for the OPC states “an additional weighting is applied on
15 units with Firmware 18 or higher to account for under counting at low particle sizes and the effect of
16 carbon particles in urban air so that the output matches collocated reference detectors.”

17

18 The lower cut off for particle size observed by the OPC is 380 nm and hence a large proportion of all
19 particles are not observed by the OPC due to the particle number being dominated by the smallest
20 particle sizes (Seinfeld and Sypyros, 2016). Ultrafine particles (particles of aerodynamic diameter
21 <100 nm) were therefore not measured. However, the interest of the study was particulate mass
22 which is dominated by particle sizes that were measured.

23

24 The sensors had their data logged using Raspberry Pi 3 minicomputers. The Python script used to
25 run the OPC-N2 on the Raspberry Pi 3 is discussed and provided in Crilley et al. (2018) and makes use
26 of the py-opc python library for operating the OPC-N2 written by Hagan (2017). Together, the OPC-
27 N2, minicomputer and accompanying wires and tubing were placed in bespoke weather resistant
28 housing (dimensions ca. 30*20*10 cm). Power for both the OPC-N2 and minicomputer were
29 provided by mains power.

30

31 The OPC-N2 sensors are factory calibrated to measure PM mass concentrations representative of
32 the UK. However, in our previous study, (Crilley et al., 2018) we demonstrated that in situ calibration
33 of the sensors is required for the correct measurement of PM mass concentrations at urban
34 background sites in Birmingham, UK. The calibration in the Crilley et al. (2018) study involved both

1 scaling and a relative humidity (RH) dependent term for when the RH is greater than approximately
2 85%.

3

4 The mass concentrations from the OPC-N2 devices, in the PM_{10} , $PM_{2.5}$ and PM_{10} size bins were
5 recorded in time intervals of 10 s. For the subsequent analysis, the mass concentration data were
6 aggregated into 1 h time-bins using the mean average. In time periods which contained missing data,
7 the mean average of the available data was aggregated. All data manipulations were performed
8 using R (version 3.4.1), and the openair project package for R was used extensively for data
9 visualization (Carslaw and Ropkins, 2012).

10

11 3.3. Meteorological station

12 The local meteorology for Nairobi was measured at the same location as the urban background site
13 using a Vaisala instrument (WXT510) with the following variables measured: wind speed, wind
14 direction, temperature, relative humidity, relative humidity, barometric pressure, and rainfall with
15 an instrument temporal resolution of five minutes. The meteorology measured parameters were in
16 good agreement with other local measurements such as those observed at Jomo Kenyatta
17 International Airport (JKIA), which is approximately at an aerial distance of 10 km. The proximity of
18 the meteorological station at the urban background site to the urban roadside makes the
19 meteorological data appropriate for both sites. The data was collected at the urban background site
20 from the 2nd of February to the 6th of April 2017, covering the duration of the PM measurements.

21 3.4. OPC-N2 gravimetric mass calibration

22 The OPC-N2 mass concentrations were calibrated using gravimetric measurements of $PM_{2.5}$ and
23 PM_{10} . The gravimetric calibration measurement was carried out on the 9th February 2017 for 24 h. A
24 collocation measurement of the OPC and an Anderson dichotomous impactor (Sierra Instruments
25 Inc., USA) was set up, on the only possible date, at the background site. The impactor collected $PM_{2.5}$
26 and $PM_{10-2.5}$ particles on Teflon filters (diameter = 37 mm, pore size = 2 μm) at a total flow rate of 1
27 $m^3 h^{-1}$. PM_{10} is therefore the sum of the two size fractions ($PM_{2.5} + PM_{10-2.5}$). The chosen sample day
28 was rain free and had similar temperature and RH profiles compared to the rest of the OPC sampling
29 campaign. The filters were weighed using a mass balance before and after particulate matter
30 collection. The observed 24 h average mass concentrations of $PM_{2.5}$ and PM_{10} from the impactor
31 were 27.6 ± 6.8 and $51.8 \pm 10.3 \mu g m^{-3}$, respectively, while those recorded from the OPC 16.9 and
32 $30.6 \mu g m^{-3}$, respectively. The uncertainty in gravimetric concentrations was estimated from the
33 instrument (10%), sampling (7%) and weighing (25%) errors and that of the OPC data was the

1 standard deviation. Hence, the observed scaling factors between the OPC derived masses and
2 gravimetric analysis were 1.70 and 1.63 for PM_{10} and $PM_{2.5}$, respectively. These factors are different
3 to that observed in Crilley et al. (2017) which performed a similar gravimetric calibration procedure
4 with the OPC-N2 measuring PM at an urban roadside sites in the UK. The discrepancies in scaling
5 factors are likely due to differences in average particle densities observed in Kenya compared to that
6 observed in the UK, and also the typical RH measured in Nairobi compared to the UK measurements
7 (see discussion in next section). In particular, Nairobi PM has been shown to have a high percentage
8 of mineral dust which typically has a high density, with Gaita et al. (2014) showing the annual
9 average composition of $PM_{2.5}$ being composed of 35% mineral dust which originates from unpaved
10 roads and wind-blown dust during the dry seasons. The gravimetric analysis did not allow for the
11 calibration of the PM_1 mass concentrations because a filter sample was not generated for the
12 fraction of PM in this size range. Hence, the PM_1 size fraction calibration uses the same calibration
13 factor derived for the $PM_{2.5}$ size fraction.

14

15 The gravimetric calibration was carried out at the urban background field location, for the three
16 OPC-N2s which were subsequently used in the measurement campaign at the three field sites.
17 Hence, the calibration was most appropriate for the urban background site. Whilst the urban
18 roadside site is in close proximity to the urban background site, the roadside site is more influenced
19 by traffic related PM, hence, the average particle density at the roadside site is likely different to the
20 urban background site. Likewise, the rural background site is likely to be far more influenced by
21 mineral dust than the two urban sites. Hence the gravimetric calibration at the urban background
22 sites only provides an estimate calibration for the urban roadside and rural background sites.

23

24 Only one gravimetric calibration was carried out during the study period due to the lack of resource
25 for further calibrations. If the PM composition varied significantly over the study period, then the
26 true calibration factor will also change. Hence, the calibration factor used should be treated as an
27 estimate for the whole study period because changes in PM composition lead to changes in particle
28 refractive index, and therefore, the scattering pattern which is measured by the OPC to estimate
29 particle size. Changes in particle density, due to compositional changes, also affects the particle mass
30 calculated from the particle size. It is noted, for future studies it would be beneficial to have multiple
31 gravimetric calibration points to check for continuing accuracy of the OPC-N2 sensors throughout
32 the campaign.

33

1 **3.5. Measured particle mass dependence on relative humidity**

2 As detailed in Crilley et al. (2018), under UK conditions, the OPC-N2 device is sensitive to variations
3 in RH when the RH exceeds ca. 85%. Crilley et al. (2018) suggest the RH dependence is due to the
4 hygroscopic properties of particles that result in significant water mass being taken up by PM at high
5 RH. This hygroscopic dependence can be modelled using a calibration that uses the κ -Kohler
6 parameterization of aerosol hygroscopicity (Petters and Kreidenweis, 2008). The average κ
7 parameter values for the surface of the Earth in Africa ($\kappa = 0.15 \pm 0.12$) are lower than for Europe ($\kappa =$
8 0.36 ± 0.16), signifying that the rural background hygroscopicity is much less in Africa compared to
9 Europe (Pringle et al., 2010). It is noted that composition of urban PM will have different hygroscopic
10 properties to the average rural background. However, PM derived from urban emissions are likely to
11 be less hygroscopic than rural PM; therefore, the rural estimates provide a useful upper estimate of
12 particle hygroscopicity in urban centres. All locations used in the study period typically have RH less
13 than the 85% threshold. However, it is noted that the RH dependent measurements shown in Crilley
14 et al. (2018) were performed in the UK whereas these measurements were performed in Kenya.
15 There may be significant differences between aerosol compositions, and hence hygroscopicities, in
16 these two countries albeit both urban areas (Birmingham and Nairobi) will have significant vehicular
17 influence. Measurements of RH at the Kenyan urban background site show that RH was only equal
18 to or greater than 85% less than 1% of the time. Furthermore, there is no significant dependence of
19 either the observed $PM_{2.5}$ or PM_{10} mass concentration upon RH (see supplementary figures 1a and
20 1b), this is consistent with low hygroscopicity aerosols. The measurement period of work reported in
21 this paper was in the Kenyan dry season with very few rain events, it is noted that if low cost sensors
22 are to be used in the wet season in Kenya then the RH will likely be greater than 85% during
23 significant periods and the hygroscopicity effect will likely need to be accounted for to obtain good
24 measurements.

25 **4. Results**

26 **4.1. Site meteorology**

27 Figure 1d provides the wind rose for the measurement period and Table 1 provides the statistical
28 summary data for the measured meteorological variables during the study period. The wind came
29 predominantly from the northeast with a mean average wind speed of 1.9 m/s. The measurement
30 period was largely dry but there were rain events on the following days: 17th, 19th and 24th February,
31 and 17th and 22nd of March, see grey shaded rectangles in Figure 3. Air mass back trajectory analysis
32 using HYSPLIT confirms that the air masses arriving in Nairobi, during the measurement period, came
33 from the northeast (Stein et al., 2015). It is noted, the Nanyuki rural background field site is located

1 north to northeast of Nairobi and hence is a sensible choice for the measurement of the rural
2 aerosol loading arriving in Nairobi. The temperature and relative humidity time series data from the
3 urban background site is shown in supplementary figure S2.

4

5 **Table 1 Summary meteorological data for the urban background monitoring site in Nairobi (2nd**
6 **February – 23rd March 2017)**

	Wind speed (m/s)	Pressure (mbar at 1680 m)	Temperature (°C)	Relative humidity (%)
Minimum	0.1	827.3	15.2	15.0
1 st Quartile	1.0	831.4	18.9	37.0
Median	1.6	832.4	21.5	51.0
Mean	1.9	832.4	22.1	51.4
3 rd Quartile	2.5	833.4	25.2	66.0
Maximum	10.5	836.4	30.7	90.0

7

8 **4.2. Particulate matter measurement**

9 PM data was collected at the three sampling sites over the time period inclusive of 02/02/2017 and
10 24/03/2017. Figure 2 provides the time series data for the PM₁₀, PM_{2.5} and PM₁ data over the whole
11 measurement campaign. Gaps in data at specific sites are either due to the colocation of two or all
12 three instruments at one site for cross calibration purposes, due to power failure requiring
13 instrument restart or OPC malfunctioning.

14

15 The inter OPC-N2 precision was measured once during the campaign by co-locating the three
16 instruments at the urban background site for 3 days for side by side sampling. The three instrument
17 colocation was carried out during at the start of the campaign (16/02/2017 – 18/02/2017). Two
18 OPCs were collocated together at the urban roadside site near the end of the campaign (04/03/2017
19 – 27/03/2017). All instruments gave very similar readings during both co-location periods, the inter-
20 instrument precision gave a coefficient of variance of $8.8 \pm 2.0\%$ in the PM_{2.5} fraction, with no
21 degradation in inter instrument precision observed over the sampling period. This coefficient of
22 variance is better than observed in Crilley et al. (2018) but this is expected because of the lower RH
23 conditions in Nairobi (see later discussion).

24

1

2 **Figure 2** Hourly time series data showing PM₁₀, PM_{2.5} and PM₁ mass concentrations at the three
3 study locations. Red line = urban roadside, black line = urban background and blue line = rural
4 background. Where multiple OPC-N2 devices were measuring in the same location at the same time,
5 the average is provided. The grey shading represents rain events as measured at the urban
6 background location.

7 Continuous monitoring at all three sites was achieved for a fortnight in the period 18/02/2017 to
8 04/03/2017. This period will henceforth be referred to as the intensive period, whereas, the total
9 measurement campaign will be referred to as the campaign period. The number of monitoring days
10 for the urban roadside, urban background and rural background monitoring sites during the
11 campaign period were 40, 29 and 25 days, respectively.

12

13 Table 2 provides the average PM₁, PM_{2.5} and PM₁₀ mass concentrations observed at the three sites
14 during the campaign period. An identical table for the intensive period is included in the
15 supplementary material, see Table S1. The percentage of daily exceedances of daily PM_{2.5} and PM₁₀
16 as per WHO guidelines are also provided, however, to date there is no set guidelines of PM₁. All
17 measurement sites exceeded the WHO daily guidelines for both PM_{2.5} and PM₁₀ for some of the days
18 sampled. The urban roadside site exceeds the WHO guidelines on most days (85% for PM_{2.5} and 90%
19 for PM₁₀). Furthermore, on many days (13% for PM_{2.5} and 40% for PM₁₀) the urban roadside site
20 exceeds the WHO guidelines by at least twice as much. The urban background site has fewer
21 exceedances, compared to the urban roadside site, with daily exceedances occurring approximately

one third of the time. The urban background site is at an elevated position, which largely removes the direct influence of local sources of PM pollution. As such, it can be assumed that the PM mass concentrations observed at this location represent a lower limit for the ground level PM concentrations throughout Nairobi, since most PM emissions will be due to ground level sources such as vehicle emissions, fires, local industry and others. The rural background site has no daily exceedances in the PM₁₀ size fraction but exceeds the PM_{2.5} guidelines 12% of the time.

During the two-week intensive campaign, there was a period of elevated PM mass concentration observed in PM₁, PM_{2.5} and PM₁₀ size fractions centred around the 23rd February. The elevated PM was observed in all three sites; therefore, it likely represents a long-range pollution event. Correspondingly, the average PM mass concentrations and percentage of WHO exceedances are higher during the intensive period compared to the whole measurement campaign, see Table S1.

Table 2 Mean average PM mass concentrations (PM₁, PM_{2.5} and PM₁₀) and daily exceedances of the WHO PM guidelines (PM_{2.5} and PM₁₀) observed at the three measurement sites during the campaign period. ¹WHO guidelines for daily PM₁₀ and PM_{2.5} are 50 and 25 µg/m³, respectively

Measurement location	Measurement days (number)	Average PM ₁ mass concentration (µg/m ³)	Average PM _{2.5} mass concentration (µg/m ³)	Average PM ₁₀ mass concentration (µg/m ³)	% daily exceedance PM _{2.5} s ¹	% daily exceedance PM ₁₀ s ¹
Urban background	29	16.1	24.8	53.0	31.6	39.5
Urban roadside	40	23.9	36.6	93.7	85.0	90.0
Rural background	25	8.8	13.0	19.5	12.0	0.0

Whilst there is insufficient temporal data to provide a yearly average value for PM_{2.5} and PM₁₀ mass concentrations for the three sites, the annual average values can be estimated from the data set using the average values provided in Table 2. These values are likely to be upper estimates for the yearly values because the measurements were obtained in period with little precipitation, thereby minimizing the degree of wet deposition of the PM. For instance, Gaita et al. (2014) showed that Nairobi's short rainy season (typically October – December) suppresses PM concentrations at the urban background site by approximately 50%. Notwithstanding the seasonal rain consideration, the

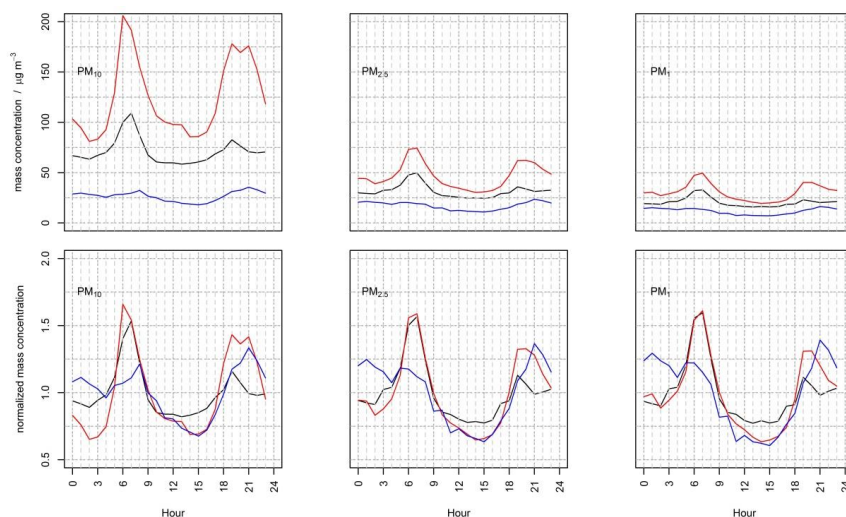

1 average PM mass concentration observed in this study suggests that that the WHO
2 recommendations for annual $PM_{2.5}$ and PM_{10} are likely exceeded at both the urban background and
3 urban roadside locations. For the urban background site, the measured average $PM_{2.5}$ and PM_{10}
4 mass concentrations exceed the annual WHO recommendations by factors of 2.5 and 2.7,
5 respectively. Whereas for the urban roadside site they exceed recommendations by 3.7 and 4.7,
6 respectively. These significant exceedances for both the urban roadside and urban background sites
7 suggests that most of Nairobi's population will be subjected to outdoor air pollution far in excess of
8 the WHO recommendations for annual exposure. Figure 3 provides the box and whisker plots for the
9 hourly averaged $PM_{2.5}$ and PM_{10} data for the three measurement sites, highlighting the proportion of
10 the days which exceed the WHO annual and daily recommendations.

1

2 **Figure 4** Diurnal variation in PM_{10} , $PM_{2.5}$ and PM_1 mass concentration measured at the three field
3 sites during the whole campaign period. Top panels show the measured concentrations. Bottom
4 panels shows the mass concentrations that have been normalized to the average mass
5 concentration

6

7

8

9 Figure 4 provides the mean average diurnal hourly profiles of the PM_1 , $PM_{2.5}$ and PM_{10} mass
10 concentrations for the three measurement sites during the whole campaign period. There is clear
11 diurnal variation observed at all the sites, two distinct peaks are observed in the two urban locations
12 during the morning (ca. 05:00 – 10:00) and the evening (ca. 18:00 – 24:00) which correspond to the
13 Nairobi peak traffic periods. The normalized data shows that the traffic related structure is very
14 similar in both the urban background and urban roadside sites indicating that the traffic related PM
15 pollution is the dominant source at both sites. The rural background site also shows diurnal
16 variation with some indication of a traffic related signal at similar times to the urban sites, especially
17 in the $PM_{2.5}$ size fraction. However, overall the rural diurnal cycle appears to largely correspond to
18 solar insolation suggesting the dominant factor affecting the rural mass concentrations is the height
19 of the local boundary layer which decreases in the night time and increases with greater solar
20 insolation.

21

22 Through comparison of the urban roadside, urban background and rural background hourly
23 averaged data, it is possible to generate estimates of urban increments and roadside increments

1 relevant for Nairobi using a 'Lenschow' type approach (Lenschow et al., 2001). For the intensive
2 period the urban and rural increments are calculated for both the PM_{10} , $PM_{2.5}$ and PM_{10} mass
3 concentrations, see Figure 5. The urban increment is calculated by subtracting the hourly average
4 values of the rural background site from the urban background site. During the intensive period,
5 analysis of the air mass back trajectories indicates that the regional wind direction was almost
6 exclusively from the northeast. Hence the Nanyuki rural background site is a good representative of
7 the rural background that impacts upon Nairobi.

8 The roadside increment was calculated by subtracting the hourly average values of the urban
9 background site from the urban roadside site. It is noted that the chosen roadside measurement
10 site is particularly busy with vehicles, compared to many other non-highway streets in Nairobi. In
11 particular, the site is a popular Matatu (14 seat passenger vans) terminal with multiple vehicles idling
12 at any point during the day. Therefore, the roadside increment obtained using this location likely
13 represents a value close to the upper boundary for Nairobi roads.

Figure 5 Box and whisker plots of urban and roadside increment of PM_{10} , $PM_{2.5}$ and PM_1 calculated for Nairobi. Data was taken from the intensive campaign period when the urban background, urban roadside and rural background sites were all measuring simultaneously. Hourly averaged mass concentration data is used

The urban and roadside increments are significant for all the investigated PM size fractions. A statistical summary of the roadside and urban increments for the PM_1 , $PM_{2.5}$ and PM_{10} size fractions are given in Table 3.

Table 3 Summary of roadside and urban increments for the PM_1 , $PM_{2.5}$ and PM_{10} size fractions measured during the intensive period.

	Roadside Increment ($\mu\text{g}/\text{m}^3$)			Urban Increment ($\mu\text{g}/\text{m}^3$)		
	PM_1	$PM_{2.5}$	PM_{10}	PM_1	$PM_{2.5}$	PM_{10}
Minimum	-4.3	-6.1	-31.7	-20.1	-26.9	-23.6
1 st Quartile	7.3	10.5	22.2	1.0	2.2	19.5
Median	12.6	18.3	43.3	4.7	7.1	33.1
Mean	18.9	22.9	58.1	5.2	8.2	36.6
3 rd Quartile	20.7	30.0	83.4	8.7	13.2	48.2
Maximum	95.5	123.9	292.6	51.2	86.3	258.0

During the intensive period, the mean average roadside increment is 57.2, 47.5 and 48.1 % of the mean roadside mass concentration, in the PM_1 , $PM_{2.5}$ and PM_{10} size fractions, respectively.

The spatial variation in PM emissions, in the different size fractions, can be assessed at the urban background and urban roadside sites using bivariate polar plots, which provide information on the variation of PM mass concentration with wind direction and speed, see Figure 6 (Carslaw and Beevers, 2013). The urban background and urban roadside sites are sufficiently closely collocated (< 0.5 km apart) that the wind data acquired at the urban background site is applicable to the urban roadside site. Wind direction data was not available for the rural background site, so analysis of the spatial variation was impossible at this site.

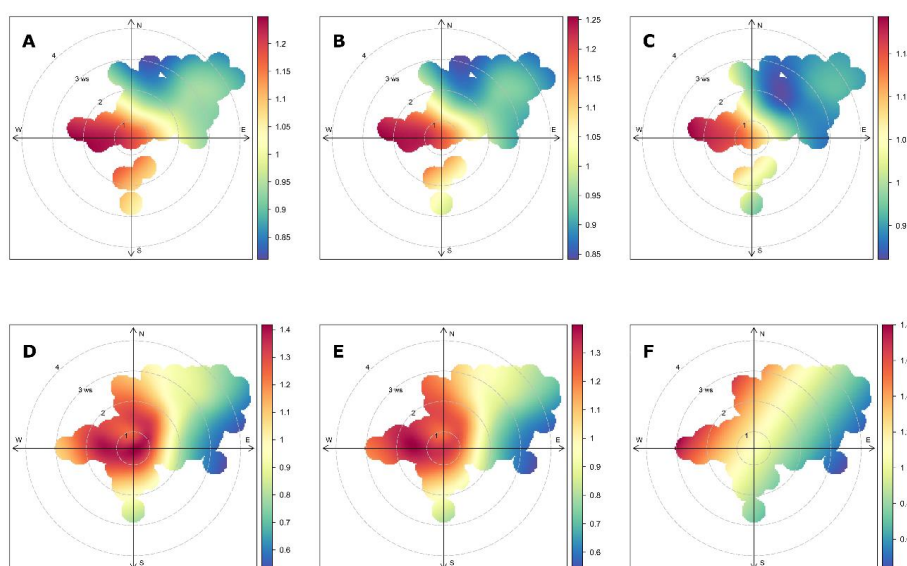

Figure 6 clearly shows significant variation of PM mass concentration at both urban sites, which are dependent upon the wind conditions. The urban background site shows broadly similar behaviour in the spatial variation of the PM_1 , $PM_{2.5}$ and PM_{10} size fractions. The peak in concentrations are observed at low wind speeds and when the wind comes from the west and south. This wind direction dependence is consistent with the close proximity of the major highway A104 'Nairobi-

1 Malaba Road', which passes close to the site in the direction of high PM concentrations. The diurnal
2 profiles and roadside increments discussed earlier combined with the wind dependence highlights
3 the role of roads in Nairobi as the major source of PM in all size fractions studied. Since the site is
4 within Nairobi's Central Business District (CBD), there are other significant roads nearby as well, but
5 the A104 has the greatest fleet density.

6 The urban roadside site also shows distinct variation in pollutant concentrations with wind speed
7 and direction. In the PM_{10} size fraction the greatest concentrations are seen to the northwest and
8 smallest to the southwest with a steady reduction between these two extremes. The $PM_{2.5}$ and PM_1
9 size fractions show a more complex behaviour with highest concentrations at low wind speeds and
10 the north and west directions. The urban roadside location is surrounded by small roads and lower
11 traffic speeds compared to the highways, for example the A104. The lower traffic speeds likely lead
12 to less non-tail pipe emissions from dust resuspension and hence there are less local PM_{10} particles
13 when compared to the urban background site. Whereas the localized $PM_{2.5}$ and PM_1 concentrations
14 are likely due to the heavily congested local roads on which Matatus and other vehicles are often left
15 idling leading to high tail pipe emissions, which are typically in the smaller PM size fractions (Pant
16 and Harrison, 2013).

17

18

1 **Figure 6** Bivariate (polar) plots of PM in different size fractions at urban background (UB) and urban
2 roadside (UR) sites. Panel descriptions A) PM_1 UB, B) $PM_{2.5}$ UB, C) PM_{10} UB, D) PM_1 UR, E) $PM_{2.5}$ UB
3 and F) PM_{10} UR. The PM mass concentration data in each plot are normalized to allow for easy
4 comparison between the different sites and PM size fractions investigated. However, note the scale
5 bars are different for each panel to allow for easier interpretation.

6

7

8

1

2 Figure 7 provides the distributions of the ratio between the coarse and the fine PM mass fractions at
 3 the three field sites during the campaign period. Whilst each site shows distinct variation, with large
 4 interquartile ranges, in the reported coarse:fine ratio, which is dependent on the time of year and
 5 time of day, the median ratios at each site are distinct, with the ratio at the urban roadside, urban
 6 background and rural background sites being 1.6, 1.3, and 0.5, respectively. At the roadside site, the
 7 median coarse:fine mass ratio is almost triple that observed at the rural background; this is
 8 consistent with the dominant source of PM at the roadside site being the resuspension of large dust
 9 particles by non-exhaust emissions from vehicles. At the rural site, the PM size distribution has a
 10 greater ratio of fine material consistent with the rural site having a signature of regional background
 11 PM. The ratio of coarse:fine PM at the urban background site is intermediate between the roadside
 12 and rural background sites which suggests that this site is effected significantly by both the regional
 13 background and the urban road PM sources. These insights into the coarse:fine PM ratio is
 14 consistent with the roadside and urban increments, shown in Figure 5 and discussed previously.

15

16 **Figure 7** Ratio of the coarse ($PM_{10} - PM_{2.5}$) to fine ($PM_{2.5}$) fraction of PM

17

18 **4.3. Comparison with previous measurements**

19 To the best of our knowledge, there has been no previous literature study to date utilising calibrated
 20 low cost sensors to measure PM in Nairobi. Furthermore, it is difficult to make comparison with

1 previous Nairobi based PM studies because of the differences in the temporal resolution of the data
2 and campaign durations used in this study compared to past measurements.

3 The most comparable study of PM_{2.5} would be the work of Gaita et al., (2016) which also recorded
4 the levels of PM_{2.5} at the University of Nairobi (urban background site). The urban background
5 average of PM_{2.5} during this study's campaign period was 24.8 µg/m³ compared to Gaita et al.,
6 (2016) mean average of 9.8µg/m³, showing a significant increase of 253%. The sampling time
7 window used in Gaita et al., (2016) study was between August to September 2007 which is distinct
8 from the February to March 2017 period of this study. Both of these study periods were largely dry,
9 with low precipitation levels, thereby suggesting PM deposition would have been similar between
10 the two studies. The significant increase in measured PM_{2.5} could be due to several reasons. Firstly,
11 there could be seasonal differences between August/September and the February/March sampling
12 periods of the two studies; however, the study of Gaita et al. (2014) suggests the urban background
13 concentrations of PM_{2.5} mass concentration is similar between these two time periods. The regional
14 background PM loading may have increased during this time period, potentially due to increasing
15 regional aridity caused by climate change leading to more dust generation (Greve et al., 2017). There
16 is almost ten years difference in the times of this study compared to Gaita et al. 2016, in this time
17 Nairobi has undergone significant increases in population and urbanization with correspondingly
18 higher use of motorization and fuel. Using UN population data (UN, 2014), the population of Nairobi
19 is well modelled by equation E1, in which Y is year date, and p is the population in thousands, which
20 suggests that the population of Nairobi has increased by 148% from 2007 to 2017.

$$21 \quad p = 2.33 \times 10^{31} \exp(3.91 \times 10^{-2} \times Y) \quad (E1)$$

22 Hence, the population increase alone cannot account for the increase in PM concentration. The
23 pollution production capability per capita could have increased, which is very likely because of the
24 increased rates of motorization and fuel use. If we assume that the increase in PM is solely due to
25 population increase and per capita pollution, it suggests that in 2017 the average citizen is 70% more
26 polluting than the average citizen in 2007.

27 The Egondi et al. (2016) study of PM_{2.5} in two slums in Nairobi reported much higher values of 166
28 µg/m³ and 67 µg/m³ for two different slum areas within Nairobi. These values are much higher than
29 the average PM_{2.5} values from this study; Egondi et al. stated that the reason for such high levels of
30 PM_{2.5} stemmed from the local situation and distinct sources of PM within the two slums. This study
31 used a TSI optical particle counter, which was placed 1.5 m above ground level. Therefore, these
32 measurements were likely highly influenced by re-suspended dust.

1 Although Kinney et al., (2012) measured $PM_{2.5}$ levels at four roadside locations, the sampling
2 window was only 11 hours and therefore it is not possible to directly compare this study to it.
3 However, considering the diurnal variation in PM found in this study, both investigations measured
4 similar $PM_{2.5}$ levels. Kinney et al., (2012) recorded daytime concentration ranges of $10.7 \mu\text{g}/\text{m}^3$ and
5 $98.1 \mu\text{g}/\text{m}^3$ for a rural and urban roadside site, respectively, compared to ca. $25 \mu\text{g}/\text{m}^3$ and ca. 150
6 $\mu\text{g}/\text{m}^3$ for this study. Again, the increase between sampling years may be a reflection of the
7 increased population, vehicular traffic and rapid urbanisation.

8 5. Discussion

9 In this study, we have shown that Nairobi currently has very high levels of PM mass concentration in
10 the PM_{10} , $PM_{2.5}$ and PM_{10} mass fractions. These measurements were conducted using low cost
11 calibrated OPC-N2 sensors. The measured $PM_{2.5}$ and PM_{10} concentrations at the urban roadside and
12 urban background sites both regularly exceeded the WHO daily limits and very likely exceed the
13 annual limits. In particular, the roadside site often showed concentrations of double the WHO
14 guidelines. These concentrations will very likely be causing significant harm to the population of the
15 Nairobi.

16 The negative health effect of PM is linked to the level of exposure experienced by the patient. This
17 paper and others (e.g. Gaita et al. 2014) have shown that in Nairobi, vehicle emissions are the most
18 significant source of PM. Hence, in Nairobi and other similar cities, the exposure to outdoor PM is to
19 a large extent a function of ones proximity to roads. Furthermore, since traffic varies diurnally,
20 seasonally and by day of the week, personal exposure is both spatially and temporally dependent.
21 This spatial and temporal heterogeneity leads to health inequalities in cities. The urban poor who
22 are often most vulnerable to environmental risks due to lack of adequate health provision, typically
23 live in close proximity to roadways, heightening their exposure to vehicular emissions. Stemming
24 from poorly planned rapid urbanisation and inadequate service provision within these cities, those
25 that are unable to afford public transport or personal vehicles frequently walk along these pollution
26 heavy roads, only increasing their exposure periods.

27 This study only looked at outdoor air quality, it is important to stress that most air pollution deaths
28 in Kenya and SSA in general are due to poor indoor air quality. As a total number of deaths, deaths
29 related to indoor air quality in Kenya rose to 18% from 1990-2013 (Roy, 2016). In LMIC countries,
30 indoor exposure to pollutants is typically from the household combustion of solid fuels on open fires
31 or traditional stoves. These exposures increase the risk of acute lower respiratory infections and
32 associated mortality among young children; indoor air pollution from solid fuel use is also a major

1 risk factor for cardiovascular disease, chronic obstructive pulmonary disease and lung cancer among
2 adults (Muindi et al., 2016).

3

4 This study has shown that the low cost OPC-N2 sensors can be used to generate diurnal PM datasets
5 with good precision and repeatability. As noted in the methodology, it would have been preferable
6 for more cross calibration periods with the tried and tested gravimetric PM measurement but
7 resources did not allow this. In addition to more calibration points, the study could have been
8 enhanced by the inclusion of collocated calibration points for the roadside and rural background
9 sites in addition to the urban background site, since the average particle shape, size and density will
10 likely be different between the three sites because of differing PM sources and emission factors.
11 However, it is noted, that whilst it is desirable from a purely scientific point of view to have more
12 inter-comparison with reference grade equipment; every inter-comparison adds significant
13 additional cost to the project both in terms of consumables for the gravimetric analysis (including
14 the cost of analytical grade filters and accompanying laboratory supplies), and the cost in
15 manpower. Many other cities in SSA and other LMIC countries do not have the resource that Nairobi
16 does in having a gravimetric sampler. These additional costs required for highly accurate scientific
17 results would likely make the low cost sensors not so very low cost after all, and hence bring into
18 question their unique selling point (USP).

19 Whilst this paper focused on PM pollution, it is noted, that there are serious risks to health not only
20 from exposure to PM, but also from exposure to ozone (O_3), nitrogen dioxide (NO_2) and sulfur
21 dioxide (SO_2). As with PM, concentrations are often highest largely in the urban areas of low- and
22 middle-income countries. Ozone is a major factor in asthma morbidity and mortality, while nitrogen
23 dioxide and sulfur dioxide also can play a role in asthma, bronchial symptoms, lung inflammation
24 and reduced lung function. Good quality measurements of these gas phase pollutants lag behind
25 measurements of PM in Nairobi, other SSA cities and LMIC cities in general. This is due to the high
26 importance of PM as an environmental risk factor but also because of the lack of good quality gas
27 analysers which are affordable and transportable.

28

29 6. Conclusions

30 Air quality in many LMIC urban centres is often poor and in many cities is getting worse due to the
31 combined pressures of increasing population, increasing urbanization, increasing vehicular traffic
32 and poor vehicle regulation. To be able to manage air pollution, good quality and long term data sets

1 are required. Unfortunately, in many LMICs the cost of certified high quality air quality
2 measurements is beyond the financial means of environmental authorities. Low cost sensors offer
3 the possibility of air quality products at significantly lower cost compared to traditional methods.
4 This paper used calibrated OPC-N2 devices to measure PM concentrations in Nairobi, Kenya in the
5 size fractions PM_{10} , $PM_{2.5}$ and PM_{10} . The data required calibration using an established gravimetric
6 approach to PM measurement. The need for calibration by trained scientists significantly increases
7 the costs associated with low cost monitoring and this cost needs to be factored in when assessing
8 options for air quality monitoring.

9 PM was measured in three locations: an urban roadside, urban background and rural background
10 site for a period of approximately two months. The data reveals that roadside and urban
11 background locations in Nairobi often exceed the WHO guidelines for daily averaged PM mass
12 concentration in both the $PM_{2.5}$ and PM_{10} size fractions. Comparison of the data with previous
13 measurements conducted in Nairobi is difficult but where comparison is possible, it appears that air
14 quality has become worse in the last ten years which is likely due to increases in population,
15 urbanisation and motorization. Comparison of the data from the three sites, following a 'Lenschow'
16 type approach, allowed for the calculation of representative roadside and urban increments for
17 Nairobi (Lenschow et al., 2001). This increment data can be used in future air quality modelling to
18 assess the likely health impact of PM pollution on Nairobi's population. The combination of the
19 diurnal PM data with local meteorology allows for simple source apportionment of the PM. The
20 diurnal PM concentrations tracks the Nairobi rush hours, furthermore, PM peaks when the wind
21 comes from the direction of significant numbers of vehicles such as major roads and a Matatu stop.
22 These facts taken together, point towards vehicle emissions being the major sources of air pollution
23 in Nairobi, as has been previously observed in studies such as Gaita et al. 2014. The coarse PM
24 fraction increases at roadside compared to urban background site suggesting that non-exhaust
25 vehicle emissions make up a significant amount of the vehicle emissions.

26 In summary, the low cost sensors used in this study provided much useful data for assessing air
27 quality in Nairobi at an equipment cost significantly lower than that of traditional instruments. Low
28 cost sensors have great potential in other country settings and could be used for long term sampling
29 if the appropriate calibrations are performed.

30 Acknowledgements

31 Leigh Crilley and Robin Price are thanked for their help in optimizing the OPC-N2 monitoring
32 systems. This work was funded via an EPSRC grant (Global Challenges Research Fund IS2016), the
33 Royal Society and Royal Society of Chemistry International Exchanges Award (IE170267), and DFID

1 via the East African Research Fund (EARF) grant 'A Systems Approach to Air Pollution (ASAP) East
2 Africa'. Scientific research support by International Science Programme in Sweden to Institute of
3 Nuclear Science & Technology in University of Nairobi was appreciated.
